# Abstract

Between May and October 2001, the Washington State Department of Ecology measured flows and developed continuous stage records at five sites on the Stillaguamish River and selected tributaries. Two of the five stations were located on the South Fork Stillaguamish River, one at the U.S. Forest Service Verlot Campground, and one at Snohomish County's River Meadows Park. One station was located on the North Fork Stillaguamish River, in the Mount Baker/Snoqualmie National Forest. One station was located near the mouth of Deer Creek, a tributary to the North Fork. One station was located near the mouth of Pilchuck Creek, a tributary to the mainstem Stillaguamish River. A rating curve was also developed at one additional site on the North Fork Stillaguamish River at Oso.

The streamflow monitoring was conducted in support of a temperature total maximum daily load (TMDL) study developed by the Department of Ecology. The purpose of this TMDL was to characterize water temperature and to establish load and wasteload allocations for heat sources in order to meet water quality standards for surface water temperature in the basin.

Continuous stage height recorders and staff gages were installed, and four to six discharge measurements were taken at each site. Discharge rating curves were developed for each site by relating various stage height values to corresponding discharge measurements. Applying these rating curves over the range of stage height enabled a continuous record of discharge to be developed at each station.

Streamflow in the Stillaguamish basin followed a general pattern of dry season decline, with the exception of a several small storm events throughout the study period, and one large storm event in August, which resulted in peak flows for the entire water year.

# Introduction

Between May and October 2001, the Environmental Assessment Program of the Washington State Department of Ecology (Ecology) conducted streamflow gaging on the mainstem, North, and South Forks of the Stillaguamish River, as well as on two major tributaries. The Stillaguamish River basin is located in northwest Washington State. The basin is approximately 680 square miles in area, and includes over 4,618 miles of rivers and streams. Elevations in the basin range from sea level to about 6,844 ft on Whitehorse Mountain.

The gaging was undertaken in support of a temperature total maximum daily load (TMDL) study developed by the Environmental Assessment Program. The purpose of the study was to characterize the water temperature in the basin and establish load and wasteload allocations for the heat sources to meet water quality standards for surface water temperature. The study was initiated because of the 303(d) listings of river segments which are water quality limited for temperature (Pelletier and Bilhimer 2001).

For this study, Ecology established continuous stage height recorders at five locations in the basin; two on the South Fork Stillaguamish River, one on the North Fork Stillaguamish River, One on Deer Creek, a tributary of the North Fork, and one on Pilchuck Creek, a tributary of the mainstem Stillaguamish River.

## Sites

On the North Fork Stillaguamish River, the continuous gaging station was located above Crevice Creek in the Mount Baker/Snoqualmie National Forest, at river mile 39.0 (Figure 1, Site 1).

On the South Fork, the uppermost continuous gaging station was located across from the Mount Baker/Snoqualmie National Forest Verlot Campground, at river mile 46.5 (Site 2). The lower station on the South Fork was located at Snohomish County's River Meadows Park, approximately 4 miles southwest of Arlington, at river mile 24.4 (Site 3). On Deer Creek, the gaging station was located at a private residence approximately 0.5 miles upstream of the mouth in Oso (Site 4). On Pilchuck Creek, the gaging station was located approximately 0.5 miles above the mouth (Site 5).

In addition to the five continuous gaging stations, one instantaneous gaging station was established on the North Fork Stillaguamish River above Deer Creek in Oso, at river mile 14.5 (Site 6).

At the request of the TMDL study Project Manager, streamflow data from four existing gaging stations were also used for the project; two continuous gaging stations, and two instantaneous gaging stations. The upper instantaneous gaging station is located on the North Fork Stillaguamish River northwest of Darrington, on Swede Heaven Road at river mile 30.0 (Site 7). The lower instantaneous gaging station is located on the mainstem Stillaguamish River near Silvana, at river mile 11.2 (Site 8). The first continuous gaging station was located on Armstrong Creek at the Stillaguamish tribal fish hatchery near Arlington (Site 9). This station was decommissioned before the study period began, however data has been included through March 2001. The other continuous gaging station is located on the East Fork of Nookachamps Creek in the Skagit River basin, approximately 4.5 miles upstream of Barney Lake (not on map). Streamflow data for these additional stations are included in Appendix A.

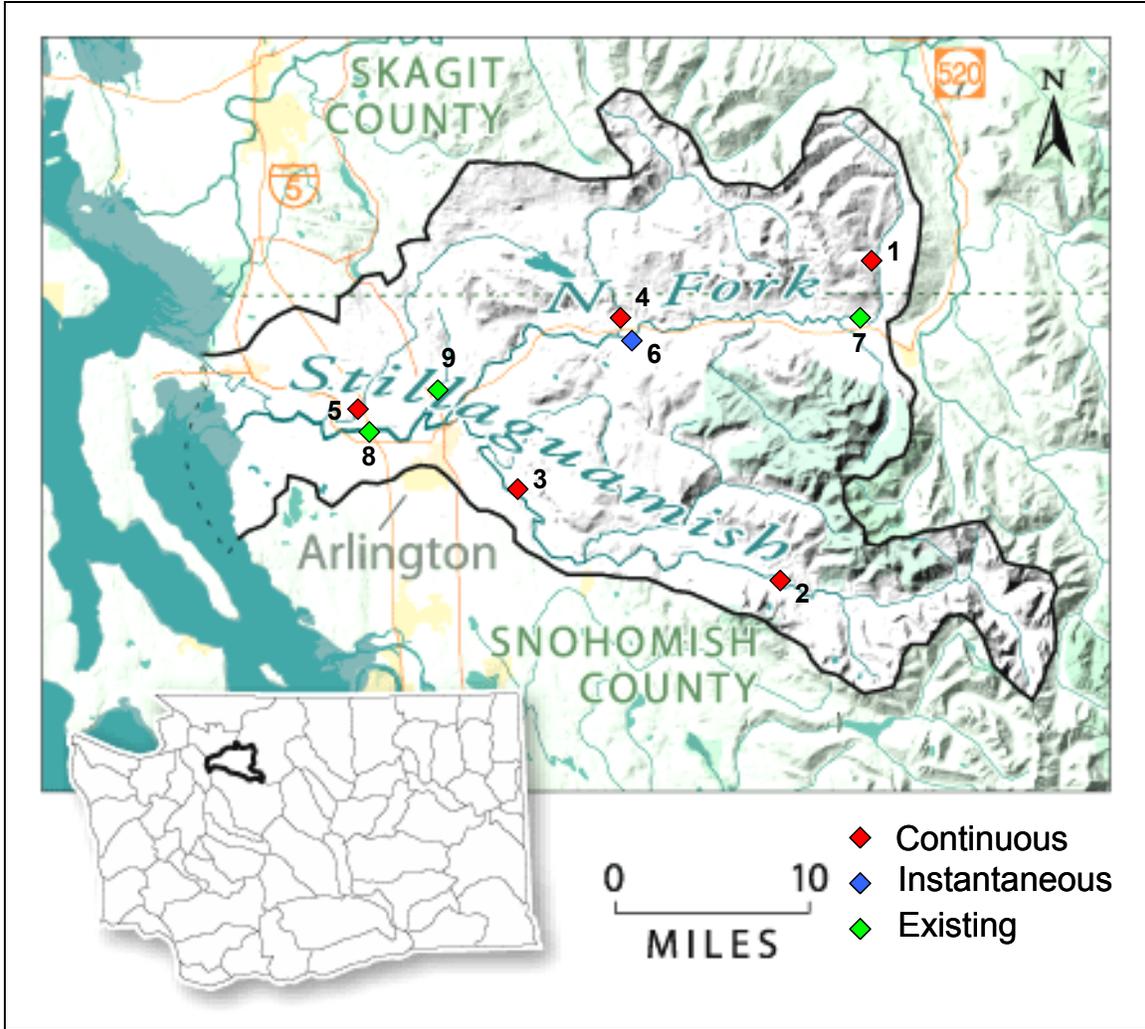

Figure 1: Map of Stillaguamish TMDL study sites.

## Methods

Each of the five continuous gaging stations was equipped with a Design Analysis pressure transducer and datalogger that recorded stage height and temperature at 15-minute intervals from June to October 2001. Four to six discharge measurements were taken at each station to establish rating curves used to calculate the average daily discharges. For the instantaneous gaging station at N.F. Stillaguamish River at Oso, four discharge measurements were taken from the 221<sup>st</sup> Ave. bridge to develop a rating curve for the station. The rating curve was then used to determine discharge associated with stage readings taken by Watershed Ecology Section staff during temperature sampling visits. For the four existing stations, established rating curves were used to give either mean daily discharge records or instantaneous discharge values associated with stage readings taken by Watershed Ecology Section staff.

Discharge measurements were made following the United States Geological Survey (USGS) mid-section method. Ecology has made minor modifications to the USGS method to accommodate its measurement equipment (Hopkins, 1999). The flow measurement cross sections were established by driving re-bar into opposing banks perpendicular to the stream flow. This allowed field staff to return to the same cross-section at different stage heights and added to the reliability of the measured discharge data. In general, the cross-sections were divided into approximately 20 cells so that no more than 5% to 10% of the total discharge passed through any single cell. The width of the individual cells varied in keeping with the 5% to 10% discharge criteria. Velocity measurements were taken at 60% of the stream depth when the total stream depth was less than 1.5 ft and at 20% and 80% of the stream depth when the depth was greater than 1.5 ft (Hopkins, 1999). The instream velocity measurements were taken using a standard USGS top set wading rod fitted for Swiffer type optical sensors and propellers. Stream discharge was calculated in the office using a specialized software program.

# Quality Assurance

## Discharge Measurements

Because the largest potential source of error involved with a discharge measurement is in the velocity measurement itself, site selection and equipment calibration are of high importance. In this study, the measured cross-sections were rated between good and poor. Based on physical conditions encountered at each site, a good cross-section assumes an error of up to 5% and a poor cross-section assumes an error of up to 8%. Depending on the selected cross-section, a minimum of the assigned error is assumed and carried forward to the final discharge calculation. An additional source of error in velocity measurements is the calibration of the Swoffer instruments. The ideal calibration value of a Swoffer propeller is 186. The Swoffer propellers used during this project were pre- and post-calibrated with values ranging from 185 to 186. A calibration rating of 186 means that for every 186 revolutions of the propeller, 10 ft of water have passed the measurement point. A calibration value of 185 underestimates the discharge measurement by less than 1%. Once a rating curve was established, discharge measurements were tracked by comparing the measured discharge values to the predicted discharge values at the same stage. The combination of propeller variations, poor cross-sections, and low-flow conditions contributed to the measured and predicted discharge differences ranging from 0.1% to over 25%. This range of difference between the measured and the predicted discharge demonstrates the ability of the rating curves to predict stream discharge for each site.

## Pressure Transducers and Staff Gages

Based on manufacturer specifications, the theoretical precision of the Design Analysis pressure transducers is less than or equal to 0.02% of the full-scale output. For the transducers used by Ecology, this precision is considered linear from 0 to 15 psi or 0 to 34.6 ft (Fletcher, 2000). During the study period, the accuracy of each probe was addressed by using staff gage versus transducer regressions. The  $r^2$  values for the regressions of transducer versus staff gage readings ranged from 0.95 to 1.00.

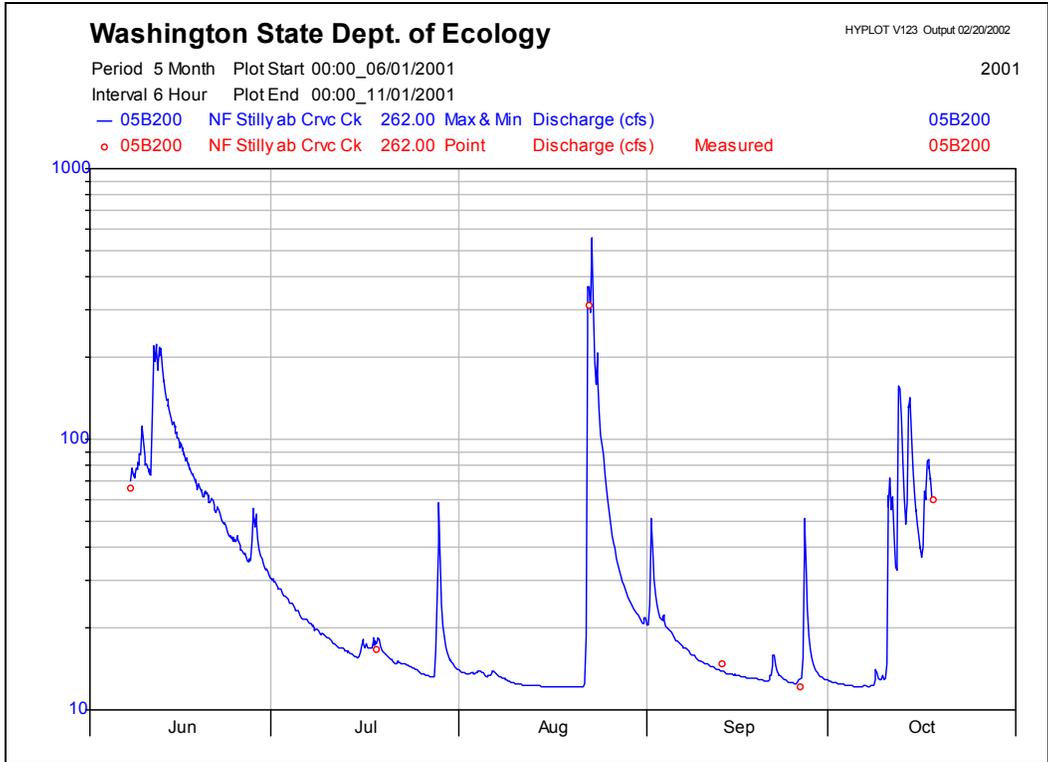

*This page is purposely blank for duplex printing*

# Results

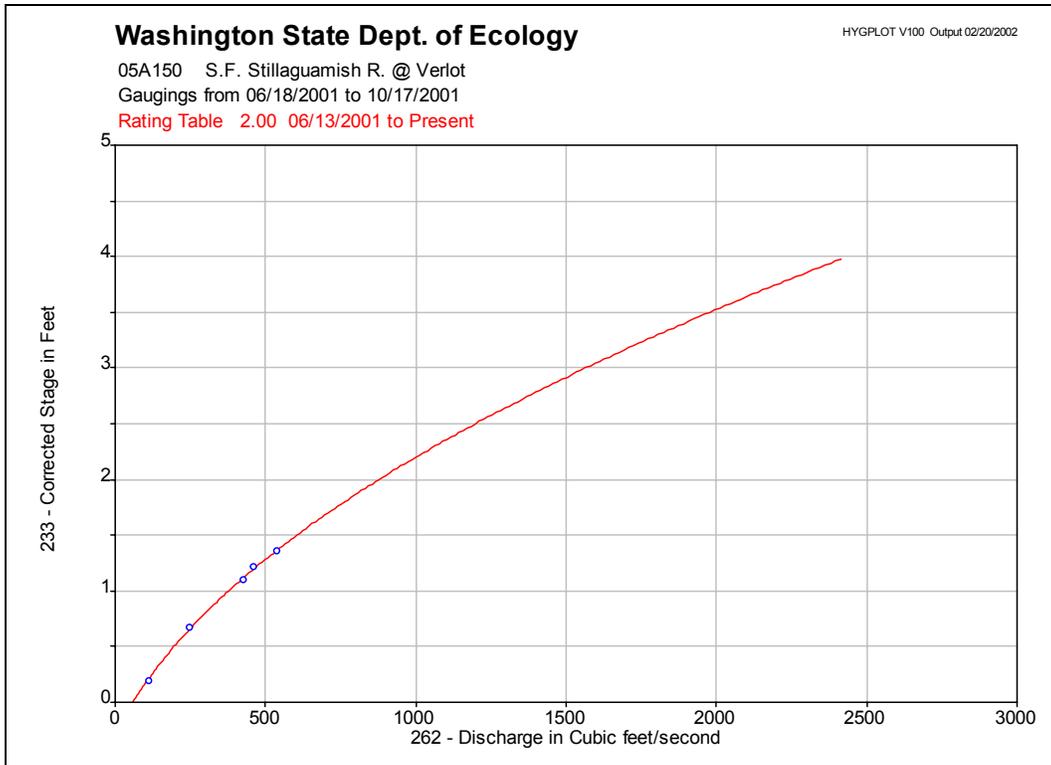

This study was designed as a summer low-flow assessment of the Stillaguamish River basin. For some of the selected sites, wide and shallow channel conditions presented unique problems with station placement, and threatened the ability to collect continuous streamflow information from static locations in the streams. In addition, two significant rainfall events occurred during the study period; one during June 11-13, and the other during August 22-24. For many rivers in Western Washington, the August rainfall event resulted in the peak streamflow for the water year. Most of the study sites were not wadable, and thus could not be measured, during high flows. As a result, most of the rating curves do not accurately cover the full range of flows. For any given gaging station, flows encountered that are over two-times the highest measured flow for that station are considered estimates.

## Site 1: N.F. Stillaguamish River above Crevice Creek

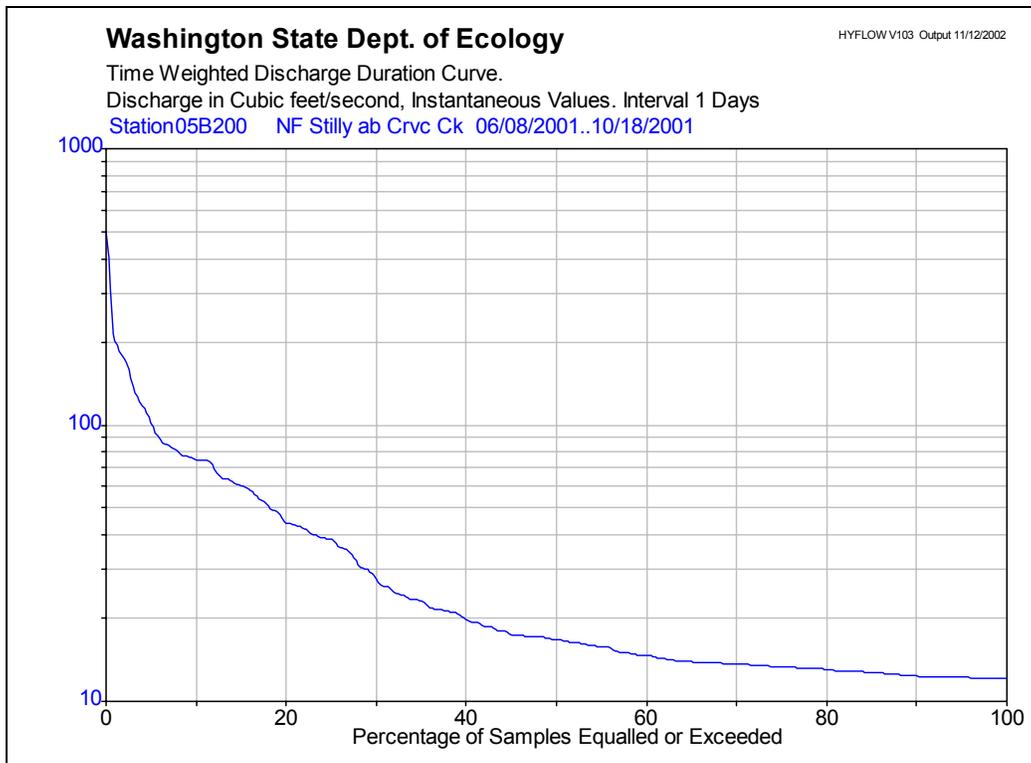

The average daily discharge for Site 1 ranged from just over 12 cubic feet per second (cfs) during dry periods in August, September and October, to over 300 cfs during an intense storm event in August. Peak flow during the study period was over 550 cfs on August 22 (Figure 2). Daily discharge averages are presented in Appendix B, Table 1. The rating curve encompassed nearly 60% of the range of discharge, with flow measurements ranging from 12 to 315 cfs (Figure 3). However, discharge exceeded the rating curve less than 1% of the time over the duration of the study period (Figure 4). The rating curve, a polynomial regression of discharge versus pressure transducer readings, had an  $r^2$  of 0.99. All six discharge measurements conducted at this station during the study period were within 10% of the flow predicted by the rating curve, and three were within 5% of the flow predicted by the rating curve. The linear regression of staff gage readings against pressure transducer readings was also quite strong, with an  $r^2$  of 1.00 (Figure 5). The overall trend in streamflow at Site 1 reflects a typical dry-period decline in discharge, with the exception of several small storm events occurring at various times throughout the study period, and the water year peak event occurring in late August.

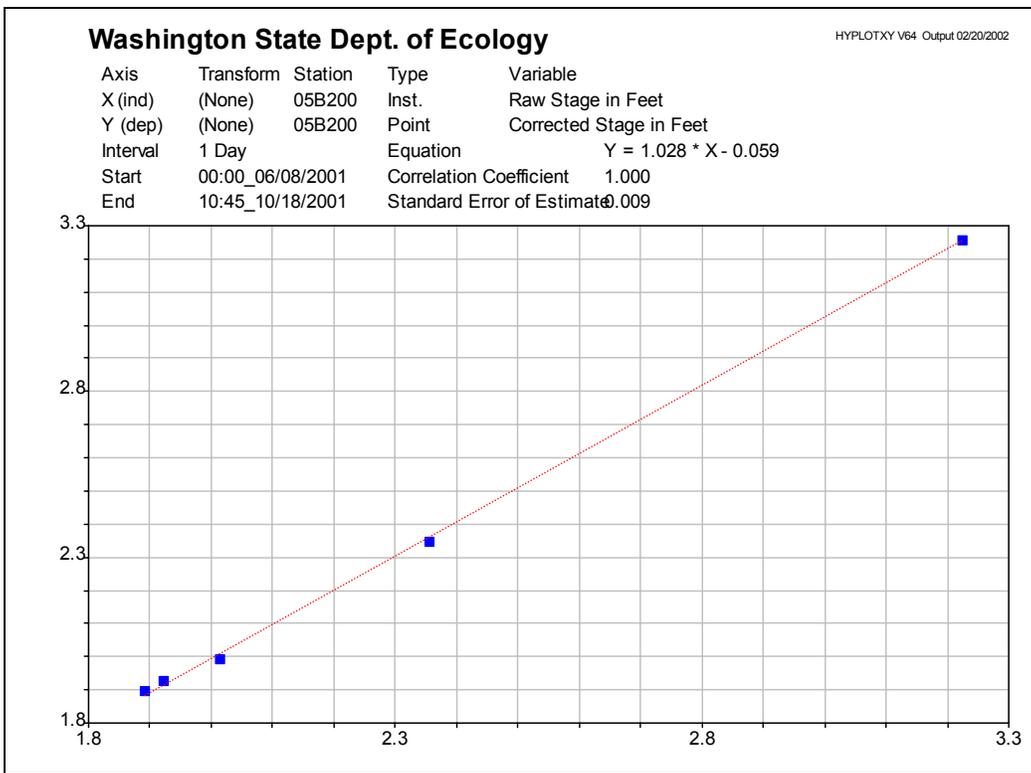

**Figure 2: Discharge hydrograph for Site 1.**

**Figure 3: Discharge rating curve for Site 1.**

**Figure 4: Flow exceedence graph for Site 1.**

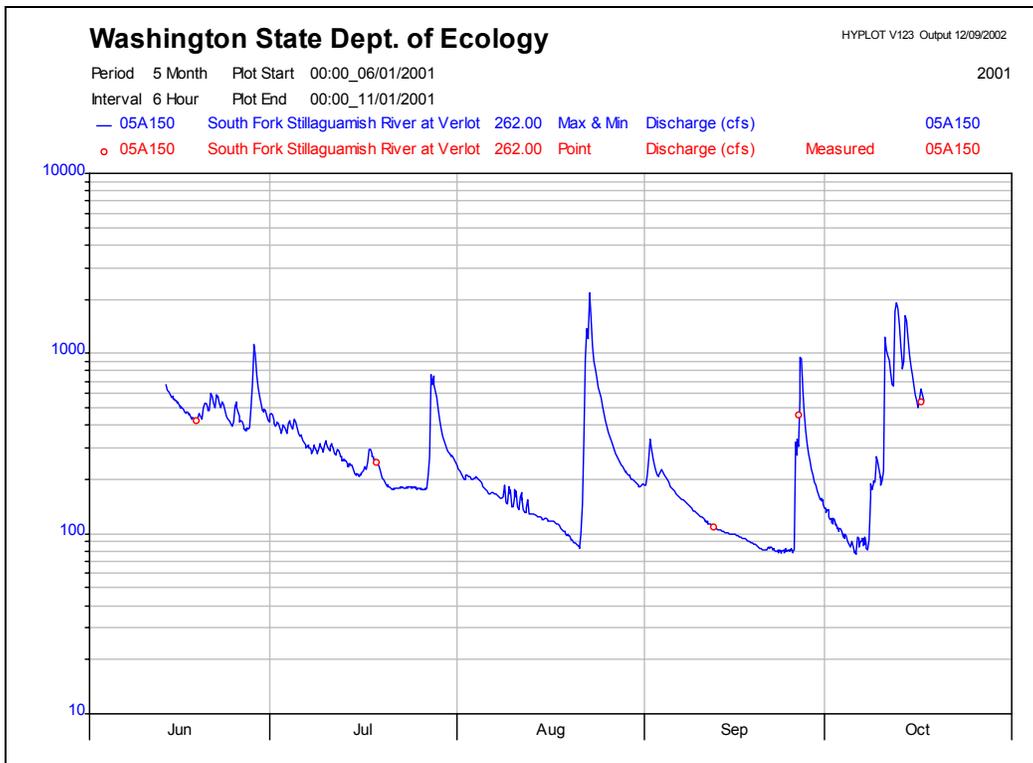

**Figure 5: Linear regression of staff gage versus pressure transducer readings for Site 1.**

*This page is purposely blank for duplex printing*

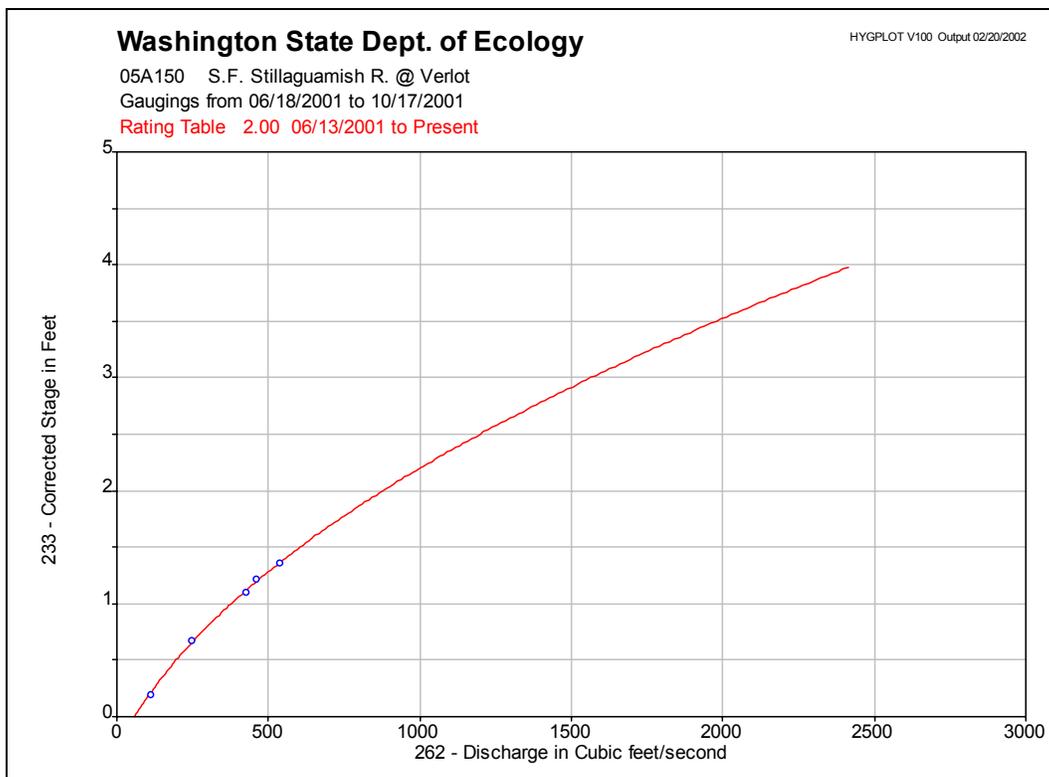

## Site 2: S.F. Stillaguamish River at Verlot

The average daily discharge for Site 2 ranged from 80 cfs during dry periods in August, September and early October, to over 1300 cfs during storm events in mid-October. Peak flow during the study period was nearly 2,200 cfs on August 23 (Figure 6). Daily discharge averages are presented in Appendix B, Table 2. The rating curve encompassed less than 25 percent of the range of flows encountered during the study period, with discharge measurements ranging from 100 cfs to 530 cfs (Figure 7). A substantial portion of the discharge data collected at this site exceeded the rating curve. A discharge of 530 cfs was exceeded more than 15% of the time over the duration of the study period (Figure 8). Channel conditions at this site, combined with the lack of an adequate bridge crossing, resulted in an inability to measure flows greater than 550 cfs. The rating curve, a polynomial regression of discharge versus pressure transducer readings, had an  $r^2$  of 0.99. All five discharge measurements conducted at this station during the study period were within 5% of the flow predicted by the rating curve. The linear regression of staff gage readings versus pressure transducer readings was strong during low-flow conditions, but not so strong during high flow conditions, with an overall  $r^2$  of 0.976 (Figure 9).

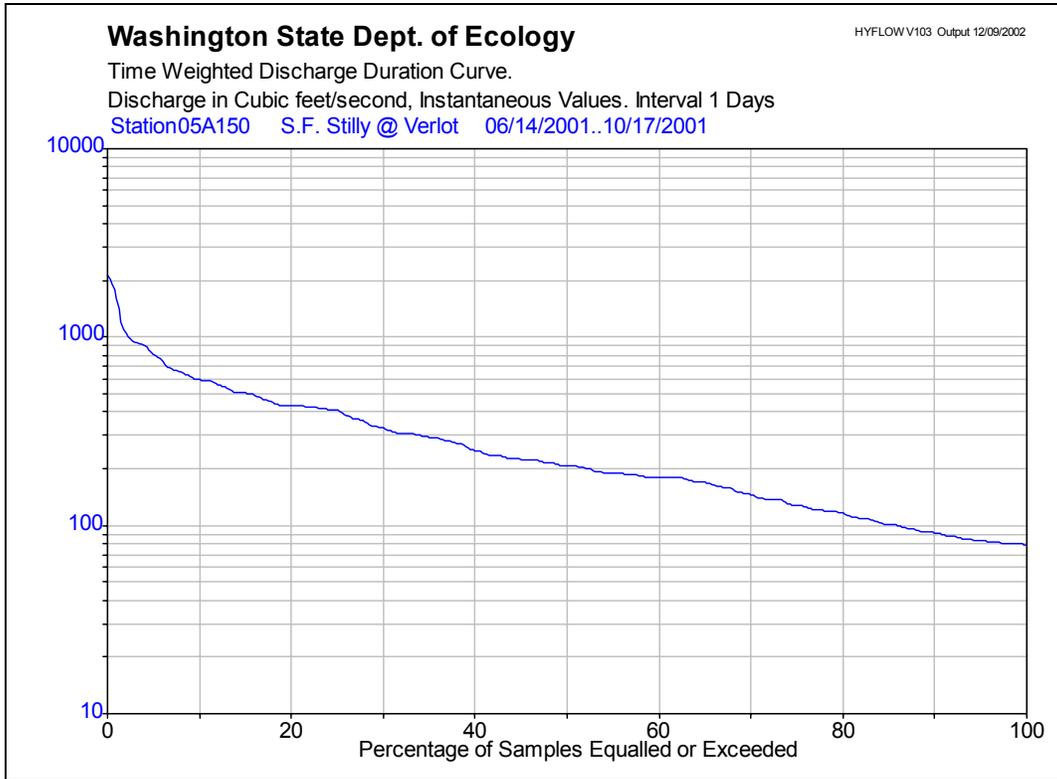

The overall trend in streamflow at Site 2 reflects a typical dry-period decline in discharge, with the exception of several small storm events occurring at various times throughout the study period, and the water year peak event occurring in late August. However, during one distinct five-day time period of the study period (August 8-12), a diurnal cycle in stage readings was encountered. This was later determined to be related to an equipment problem, and the original data was corrected. Additional discussion of this problem is included as Appendix C.

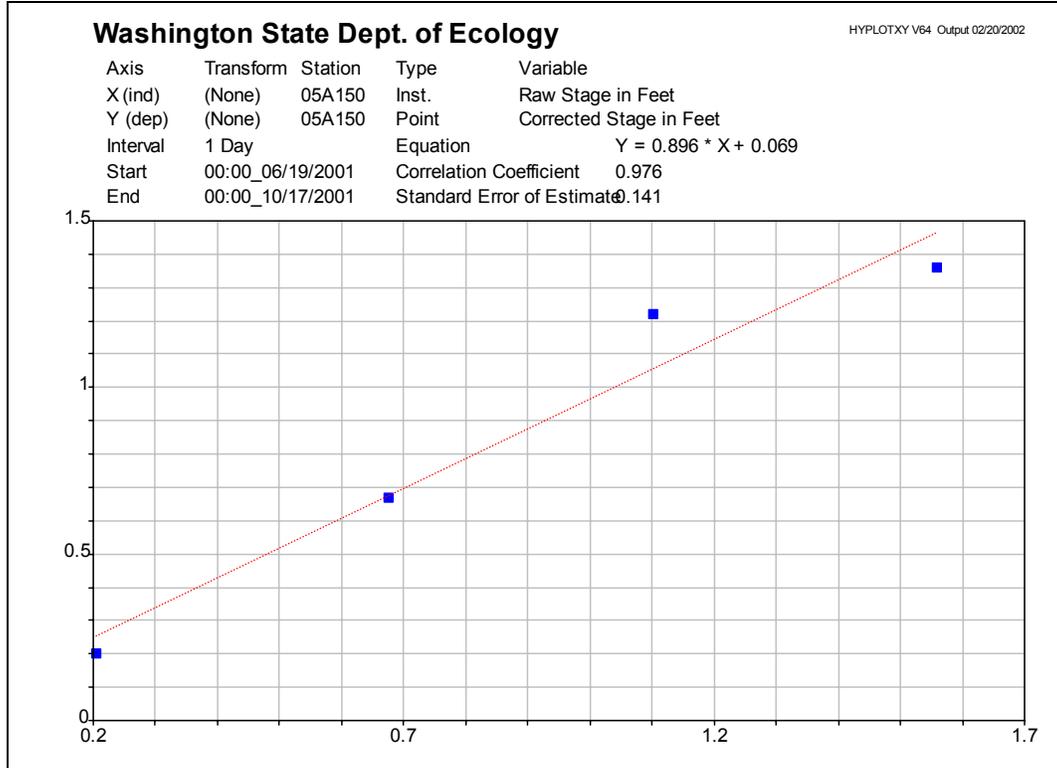

**Figure 6: Discharge hydrograph for Site 2.**

**Figure 7: Discharge rating curve for Site 2.**

**Figure 8: Flow exceedence graph for Site 2.**

**Figure 9: Linear regression of staff gage versus pressure transducer readings for Site 2.**

*This page is purposely blank for duplex printing*

## Site 3: S.F. Stillaguamish River at River Meadows Park

The average daily discharge for Site 3 ranged from around 140 cfs during dry periods in August, September and early October to 4400 cfs during a storm event in late August. Peak flow during the study period was nearly 9,500 cfs on August 23 (Figure 10). Daily discharge averages are presented in Appendix B, Table 3. The rating curve for Site 3 encompassed less than 15 percent of the range of flows encountered during the study period, with flow measurements ranging from 175 cfs to 1400 cfs (Figure 11). Channel conditions at the site, combined with the lack of an adequate bridge crossing, resulted in an inability to measure flows greater than 1,400 cfs. However, discharge exceeded the rating curve less than 10% of the time over the duration of the study period (Figure 12). Within the range of measured flows, the fit of the rating curve was very good. A log-log regression of river stage against discharge had an  $r^2$  value of 0.999 (Figure 13). All five discharge measurements conducted at this station during the study period were within 5% of the flow predicted by the rating curve. The linear regression of staff gage readings versus pressure transducer readings was stronger during low flow conditions than during high flow conditions, with an overall  $r^2$  of 0.991 (Figure 14). The overall trend in streamflow at Site 3 reflects a typical dry-period decline in discharge, with the exception of several small storm events occurring at various times throughout the study period, and the water year peak event occurring in late August.

**Figure 13: Log-Log regression of stage versus discharge for Site 3.**

**Figure 14: Linear regression of staff gage versus pressure transducer readings for Site 3.**

*This page is purposely blank for duplex printing*

## Site 4: Deer Creek at Oso

The average daily discharge for Site 4 ranged from over 30 cfs in mid-August to 1,240 cfs during a storm event in late-August. Peak flow during the study period was 2,150 cfs on August 22 (Figure 15). Daily discharge averages are presented in Appendix B, Table 4. The rating curve encompassed only 10 percent of the range of flows encountered during the study period, with flow measurements ranging from 40 cfs to 236 cfs (Figure 16). Channel conditions at the site, combined with the lack of an adequate bridge crossing, resulted in an inability to measure flows greater than 240 cfs. Discharge exceeded the rated range of flows during peak flows each month of the study period, with event peaks ranging from 364 cfs in June to 2,150 cfs during the peak event in August. This represents a fairly sizeable portion of the encountered flows, as discharge exceeded the rating curve 10% of the time over the duration of the study period (Figure 17). The rating curve, a polynomial regression of discharge versus pressure transducer readings, had an  $r^2$  of 0.999. All five discharge measurements conducted at this station during the study period were within 5% of the flow predicted by the rating curve. The linear regression of staff gage readings versus pressure transducer readings was strong throughout the range, with an  $r^2$  of 1.00 (Figure 18). The overall trend in streamflow at Site 4 reflects a typical dry-period decline in discharge, with the exception of several small storm events occurring at various times throughout the study period, and the water year peak event occurring in late August.

## Site 5: Pilchuck Creek at Bridge 626

High flows from a storm event submerged the datalogger at the Pilchuck Creek station on June 11, 2001, causing it to fail. As a result, data were not collected for a period of 35 days from June 11 through July 17. All analyses for this station are based on data exclusive of this period.

The average daily discharge for Site 5 ranged from 9.5 cfs in mid-August to 1,740 cfs during a storm event in mid-November. Peak flow during the study period was 3,970 cfs on November 14 (Figure 19). Daily discharge averages are presented in Appendix B, Table 5. The rating curve encompassed only 27 percent of the range of flows encountered during the study period, with flow measurements ranging from 12 cfs to 1,080 cfs (Figure 20). However, discharge exceeded the rating curve only 2% of the time during the study period (Figure 21). The rating curve, a polynomial regression of discharge versus pressure transducer readings, had an  $r^2$  of 0.999. Out of seven discharge measurements conducted at this station during the study period, six were within 10% of the flow predicted by the rating curve, and four were within 5% of the flow predicted by the rating curve. The linear regression of staff gage readings versus pressure transducer readings was strong throughout the range, with an  $r^2$  of 1.00 (Figure 22). The overall trend in streamflow at Site 5 reflects a typical dry-period decline in discharge, with the exception of several small storm events occurring at various times throughout the study period, and the water year peak event occurring in late August. The rise in flows with the onset of fall rains began in early- to mid-October.

## Site 6: N.F. Stillaguamish River at Oso

Continuous data collection was not conducted at Site 6. Instead, a rating curve was developed, and used to derive flows from stage readings taken during temperature sampling visits by Watershed Ecology Section staff. The stage index for this site was derived from a reference point established on a bridge over the river. River stage readings were taken by measuring from the reference point down to the water surface. Thus, as the river rose, the distance from the reference point to the water surface would decrease, and vice versa. Flows encountered during the study period ranged from just over 100 cfs in mid-September to over 840 cfs in mid-October (Figure 23). The rating curve encompassed nearly 70% of the range of flows encountered during the study period, with flow measurements ranging from 145 cfs to 655 cfs (Figure 24). The linear regression of discharge versus distance to water surface measurements had an  $r^2$  of 0.999. All four discharge measurements conducted at the site during the study period were within 5% of the flow predicted by the rating curve. The overall trend in streamflow at Site 6 seems to be a typical dry-period decline in discharge. The storm events that occurred in each of the months of June through September were not measured, nor was temperature sampling conducted during those periods.

### Discussion of Diurnal Stage Pattern at Site 2: S.F. Stillaguamish River at Verlot

During one distinct five-day time period of the study period (August 8-12), a diurnal cycle in stage readings was encountered at Site 2: S.F. Stillaguamish R. at Verlot. During these days, river stage reached a minimum around 6:00 a.m. and peaked around 6:00 p.m. This cycle was closely correlated with the diurnal water temperature cycle (Figure C-1), with  $r^2$  values for individual days ranging from 0.68 to 0.84 (Figure C-2). The diurnal fluctuations in discharge ranged from 35 to 40 cfs.

To further analyze this pattern, data for this station were compared with a downstream station; S.F. Stillaguamish R. at River Meadows Park (Site 3). During most of the study period, streamflow data collected from Site 3 closely follows that collected from Site 2, with a time-of-travel delay of approximately 8 hours during low-flow conditions. Data for the two sites were compared during two periods of apparent diurnal cycles: July 5-11, 2001 and August 8-12, 2001. During the first period (July 5-11), the rise and fall cycles in stage at Site 2 are followed by a corresponding rise and fall in stage at Site 3 (Figure C-3). However, during the second period (August 8-12), there is no corresponding cyclical rise and fall in stage at Site 3 following the diurnal rise and fall cycles in stage at Site 2 (Figure C-4). This leads the author to believe that the apparent diurnal cycle at Site 2 during August 8-12 was actually sensor error, most likely caused by the formation of an air pocket near the diaphragm of the pressure transducer. Such a scenario would result in a temperature-related diurnal cycle in pressure readings caused by thermal expansion and contraction of the air pocket. The heavy bedload present in the water column may have facilitated the dissipation of the air pocket after a short period of time, thus resuming a normal pattern in river stage.
